We present a framework for performance prediction of distributed and mobile systems. We rely on process calculi and their structural operational semantics. The dynamic behaviour is described through transition systems whose transitions are labelled by encodings of their proofs that we then map into stochastic processes. We enhance related works by allowing general continuous distributions resorting to a notion of enabling between transitions. We also discuss how the number of resources available affects the overall model. Finally, we introduce a notion ofbisimulation that takes stochastic information into account and proves it to be a congruence. When only exponential distributions are of interest our equivalence induces a lumpable partition on the underlying Markov process.

Key Words: Operational semantics, Proved transition system, Stochastic process algebra, General distributions, Performance Prediction

1. INTRODUCTION

The wide dissemination of Internet sites and the emerging paradigm of global computations based on the mobility of both code and computations make quantitative analysis of specifications as important as qualitative analysis. The need for integration of qualitative and quantitative analyses in developing complex systems since the early stages of projects has been well-accepted. Full integration is presented as a challenge for the future of computer science in [14].

An attempt at integration is given by Markovian and stochastic process algebras [24, 27, 9, 15, 30, 16, 31, 4, 11, 44, 45, 7, 8]. Process algebras are foundational calculi used to describe the concurrent and distributed structure of systems. They are made up of a few operators such as: i) \( a \cdot \) - that which describes sequential composition of actions, ii) \( a + \) - that which is the parallel composition of processes, iii) \( a \) - that which denotes a nondeterministic choice. We can view process algebras from different levels of abstraction. A common interpretation is seeing these calculi as specification languages that must be refined towards a real code. The theory of
behavioral analysis developed for process algebras (see [35]) postulates that refined
descriptions are still expressed in the same calculus but through different programs.
Then, some relations (usually a bisimulation) are established between the two des-
criptions of the system to ensure that an implementation behaves according to its
specification. We are proposing here a different use of process algebras. We inter-
pret these calculi as an intermediate language into which programs written in real
languages can be translated. For instance, languages like Facile [23], CML [39] and
Pict [42] can be easily mapped to process algebras being defined as directly extend-
ing them. We will come back to this interpretation of process algebras when we
describe our approach to quantitative analysis. For the time being, we assume the
classical interpretation as specification languages to survey stochastic extensions of
these calculi.

Stochastic process algebras enrich the actions of classical calculi with continuous
probabilistic distributions, yielding prefixes such as \((a, F)\). The distributions \(F\)
are assumed to be exponential in almost all the proposals. Unfortunately, many
phenomena that arise in practice are naturally described by non exponential dis-
tributions. Consider, for instance, the routing of a message on a network. Even
if the transfer of the message between two adjacent nodes exposes an exponential
delay, the overall routing may not. Furthermore, the industrial environment calls
for general distributions, especially in the areas of workflow models, robot systems
and ATM networks [29]. Another limitation of stochastic process algebras concerns
the modification of the syntax of the language by inserting probabilistic distribu-
tions within prefixes. Therefore, the designer must specify the intended behavior
of a system once he has in mind all the features of the architecture on which the
specification will be implemented. Otherwise, there is little hope of associating
suitable distributions with prefixes. For instance, the usage of a mobile agent or
of a remote procedure call for an interaction must be decided when designing a
system. But the fewer details needed at specification time, the better.

Our idea is to retain the advantages of stochastic process algebras without modi-
ifying the syntax of calculi that remain independent of the architectural aspects of
implementations. We only change the abstraction level at which process algebras
are interpreted. The association of probabilistic distributions with actions is then a
matter of the compiler or the interpreter of the language that necessarily has all the
relevant information about the target architecture. In this paper we concentrate on
how the compiler associates quantitative information with actions. The translation
of real languages to process algebras is out of the scope of this work (some examples
can be found in the literature [23]). We start with a description of the system given
via a process algebra allowing for code mobility. For instance, the \(\pi\)-calculus [36],
Plain-CHOCS [52], the join calculus [22], D\(\pi\) [50] and the ambient calculus [12]
have recently been proposed as an evolution of classical process calculi and they
handle mobility naturally. Here we use the \(\pi\)-calculus that permits port names to
be transmitted from one process to another in communications. Consequently, the
interconnection structure of a network is no longer static, but can vary dynamic-
ically when processes communicate. This simple conceptual extension is sufficient to
describe the mobility of processes [51].

The quantitative parameters that we associate with actions are determined on
semantic grounds along the lines of [41, 10, 40]. Here we use structural operational
semantics (hereafter abbreviated as SOS) [43], the usual way of assigning meaning to process algebras. The advantages of SOS are twofold. First, we obtain a description of the abstract machine that executes process algebra programs. Thus we have a precise description of the low-level operations needed to execute the actions of the program. Second, the SOS definitions are logical in style, mathematically simple and appealing. An example is the rule for the parallel composition of processes:

$$P \xrightarrow{\theta} P' \quad \frac{}{P|Q \xrightarrow{\theta} P'|Q}$$

The interpretation of this inference rule is that whenever the premise occurs (that is, satisfied), the conclusion occurs as well. Therefore, if $P$ can move to $P'$ via a $\theta$ action, the parallel composition $P|Q$ can perform the same action and becomes the configuration $P'|Q$.

We can now see the derivation tree of a transition (i.e., the set of inference rules applied in the derivation) as an encoding of the low-level operations of the abstract machine needed to perform the action corresponding to the transition. We thus enrich transition labels with a linearization of their deduction trees. Look again at the rule for parallel composition:

$$P \xrightarrow{\theta} P' \quad \frac{}{P|Q \parallel_{\theta} P'|Q}$$

In the conclusion label we recorded the application of the rule via the tag $\parallel_0$, where 0 means that the left component is moving. The new operational semantics is called proved [6, 18]. A version of this semantics is available for the $\pi$-calculus [20] and for the real programming languages Facile [21] and Esterel [34].

We implement a $\$ function that takes as arguments the new transition labels and provides us with a parameter expressing the execution cost (duration) of the transition. The $\$ function encodes the cost of executing the run-time support routines of the language to perform the action corresponding to a transition. Unfortunately, this is only possible when the history of the system does not influence the execution of the current transition. In other words, the system must have a memoryless property. Consequently, a function such as the one above is only suitable when durations of transitions are exponentially distributed. But we have already pointed out the limitation of exponential distributions. Therefore we need to know the enabling relation between the transitions of the system in order to handle general distributions. This allows us to keep track of the time spent by an action in the states in which it was enabled but not selected to fire. Once again the deduction trees (or better their linearizations) help us in the definition of enabling. In fact, we only need to establish a prefix relation on the strings of tags in the label of two transitions to see whether one of the two enables the other [20]. The intuitive idea is that two actions sequentially nested into a chain of prefixes are derived by using the same initial set of SOS rules. We then use this information together with the $\$ function to compute the firing distributions of transitions.

The distribution of a $\theta$ transition must be influenced by those of all the transitions fired from the states where $\theta$ was enabled. This was called enabling memory dis-
cipline in [1]. The Author proposed in [46] a stochastic extension of the \( \pi \)-calculus with general distributions, but in that case the syntax was enriched by putting distributions within prefixes.

We then introduce an enhanced version of the enabling memory discipline by using a different notion of timer associated with a transition. In classical stochastic process algebras the duration of a transition is computed by calculating the time necessary to finish its work \textit{when scheduled} on a CPU. Transitions do not consume time when the processes which perform them are not active. Therefore performance measures are ideal: any process always has a free processor for it. On the other hand, the measured performance of a system is in terms of CPU time consumption. This is a good index for comparing the performance of two systems, but it is far from being significant as far as the response time is concerned. In fact, most of the user’s waiting time is due to scheduling activities and idle times. To better express response time, we assume that the timer of a transition starts when it is enabled the first time and stops when the corresponding activity is performed, counting idle times as well. Under this interpretation of transition timers, the stochastic semantics can no longer assume that any process has its own processor. In fact, the number of available processors greatly influences the idle times and hence the response time of systems. According to the above discussion, we recover in the stochastic field the classical interpretation that interleaving descriptions actually correspond to uniprocessor architectures. Therefore, we modify the semantics of the \( \pi \)-calculus to take into account the number of available processors.

Two concurrent transitions can be executed on different processors and hence their durations are independent. If we consider the transition system representation of the two concurrent transitions, we have two computations starting from the same state and leading to the same target that differ only in the order of transition executions. This representation is adequate for a uniprocessor architecture where only one process is running at a time. This interpretation leads to the definition of enabling memory discipline as given in [46] and described above. If two processors are available, the two transitions are executed on different machines and therefore their durations must be independent. To model the number of processors available within the semantic definition of processes, we resort to higher dimension transition systems briefly outlined in [26]. Essentially, transitions can carry over as many labels as the number \( n \) of processors. We include in the transition systems the diagonal of the concurrency diamond of dimension \( n \). In this case, we only need to extend the definition of concurrency to higher dimension transitions and then apply the definition of enabling memory discipline adapted to multi-labelled transitions (see also [47]).

A major problem in using general distributions to evaluate systems is their difficult tractability. In fact, it is difficult to find closed form solutions of stochastic processes and often extensive simulation is required. To improve feasibility, we introduce a class of transition systems (that of maximal parallelism) for which the computation of performance measures, still using general distributions is easy. Unfortunately, we cannot derive \textit{exact} measures, but only upper bounds to system response time.

To ease the integration of qualitative and quantitative analyses of systems, we define a bisimulation-based equivalence to compare program performance. It ex-
tends the late bisimulation for the $\pi$-calculus [37] in the style of [33, 30, 28]. We keep track of the enabling relation between transitions when comparing two systems to get a congruence result for the full $\pi$-calculus without matching similarly to [5]. Since equivalences are often used to implement model minimization to speed up quantitative analysis, we prove that our bisimulation induces a lumpable partition on the underlying Markov process when distributions are restricted to exponential ones.

This article is organized as follows: in the next section we introduce the basic notions of the $\pi$-calculus. Section 3 defines its stochastic semantics. Enabling and concurrency are defined in Sect. 4. They are then used to compute the distributions of transitions and eventually the stochastic process associated with a transition system. Section 5 refines the enabling memory discipline introduced in the previous section to cope with the amount of resources available. The case of unbound resources is discussed as well. Section 6 introduces a notion of performance bisimulation to cope with the stochastic properties of systems. Section 7 instantiates our framework to exponential distributions. Finally, we discuss related work in Sect. 8.

2. THE $\pi$-CALCULUS

In this section we briefly review the $\pi$-calculus [36], a model of concurrent communicating processes based on the notion of naming.

Definition 2.1. $\mathcal{N}$ is a countable infinite set of names ranged over by $a, b, \ldots, x, y, \ldots$ and $\mathcal{S} = \{\tau_0, \tau_1, \tau_2, \ldots\}$ is a countable infinite set of invisible actions ranged over by $\tau_i$, with $\mathcal{N} \cap \mathcal{S} = \emptyset$. We also assume a set of agent identifiers, each with an arity, ranged over by $A, A_1, \ldots$. Processes in $\mathcal{P}$, ranged over by $P, Q, R, \ldots$ are defined as

$$P ::= 0 \mid X \mid \pi.P \mid (\nu x)P \mid [x = y]P \mid P|P \mid P + P \mid A(y_1, \ldots, y_n)$$

where $\pi$ may be either $x(y)$ for input, or $\overline{y}y$ for output (where $x$ is the subject and $y$ is the object) or $\tau_i$ for silent moves. The order of precedence among the operators is the order (from left to right) listed above. Hereafter, the trailing 0 will be omitted.

In the above definition we used a set of silent moves to distinguish their different durations. We sometimes write $(\nu x, y)P$ for $(\nu x)(\nu y)P$. Each agent identifier $A$ has a unique defining equation in the form $A(\overline{y}) = P$ (hereafter, $\overline{y}$ denotes $y_1, \ldots, y_n$), where the $y_k$ are all distinct and are the only free names in $P$.

The operational semantics of the $\pi$-calculus is defined in the $SOS$ style. We use $\mu$ as a metavariable for transition labels. We introduce set $\mathcal{A}$ of visible actions ranged over by $\alpha$ (i.e., $x(y)$ for input, $\overline{y}y$ for free output, and $\overline{y}y$ for bound output
We recall the notion of free names \( fn(\mu) \), bound names \( bn(\mu) \), and names \( n(\mu) = fn(\mu) \cup bn(\mu) \) of a label \( \mu \); only the bound names are the objects of input and of the bound output. Functions \( fn \), \( bn \) and \( n \) are extended to processes by inducing on their syntax and considering input prefixes and \( \nu \) operators as binders. We define the structural congruence \( \equiv \) on processes as the least congruence that satisfies the following clauses:

- \( P \equiv Q \) if \( P \) and \( Q \) differ only in the choice of bound names (\( \alpha \)-equivalent),
- \( (\nu x)(\nu y)P \equiv (\nu y)(\nu x)P \).

We define our enhanced labels in the style of \([17, 6, 20]\). A transition label records the inference rules used during its deduction, besides the action itself. We call proof term the encoding of the proof in an enhanced label. Finally, we introduce an \( \ell \) function that takes an enhanced label to the corresponding standard action label.

**Definition 2.2.** If \( L = \{ ||0|, ||1| \} \) with \( \chi \in L^* \), \( \mathcal{O} = \{ +_0, +_1, =_m, (\nu x), (\bar{y}) \} \) with \( o \in \mathcal{O} \cup L \), and if \( \theta \in (L \cup \mathcal{O})^* \), then the set \( \Theta \) of enhanced labels (with metavariable \( \theta \)) is defined by the following syntax:

\[
\theta ::= \bar{y} \alpha \mid \bar{\theta} \tau_i \mid \bar{\theta} (\langle ||0\bar{\theta} \alpha_0, ||1\bar{\theta} \alpha_1 \rangle)
\]

where \( \alpha_0 = x(\bar{y}) \) if \( \alpha_1 \) is either \( \bar{y} \) or \( \bar{\alpha} \), and vice versa.

Function \( \ell \) is defined as \( \ell(\bar{\theta} \alpha) = \alpha \), \( \ell(\bar{\theta} \tau_i) = \ell(\bar{\theta} \langle ||0\bar{\theta} \alpha_0, ||1\bar{\theta} \alpha_1 \rangle) = \tau \).

A \( +_0 \) (\( +_1 \)) tag means that a nondeterministic choice has been made in favour of the left (right) component. Similarly, a \( ||0 \) (\( ||1 \)) tag records that the left (right) component of a parallel composition is moving. Restriction is reported on the labels to record that a filter has been passed. We record the resolution of a matching through \( =_m \) tag, where \( m \) is the size of the data to be compared. Communications are labelled by a pair instead of a \( \tau \) to show the components which interacted (and proof of the relevant transitions). We also record in the labels the actual parameters \( \bar{y} \) of a definition because their number and size affect the instantiation cost.

Our transition system for the \( \pi \)-calculus is shown in Tab. 1. A variant of \( P \xrightarrow{\mu} Q \) is a transition which only differs in that \( P \) and \( Q \) have been replaced by structurally congruent processes, and \( \mu \) has been \( \alpha \)-converted, where a name bound in \( \mu \) includes \( Q \) in its scope \([37]\). For instance, \( x(y) \bar{y} \bar{z} . P \xrightarrow{x(\bar{y})} \bar{z} . P \{ y \mapsto w \} \) is a variant of \( x(w) \bar{w} . P \xrightarrow{x(w)} \bar{w} . P \). The transitions in the conclusion of each rule stand for all their variants. The \( Com_1 \) and \( Close_1 \) rules are obvious and are therefore omitted.

---

1The effect of a bound output is vanishing a \( \nu \) operator. Consider for instance the transition \( Q = (\nu z) x . P \xrightarrow{\bar{x} \bar{z}} P \). The intuition behind this operation is to make the private name \( x \) of \( Q \) available to the external environment. In fact, an operator \( \nu \) can be interpreted as a delimiter of an environment, while the bound output is an open of that environment. This is why the bound output is sometimes referred to as scope extrusion in the literature.
\[ \text{Table 1} \]

\textbf{Proved transition system for the } \pi\textbf{-calculus.}

\[ \text{Act: } \pi.P \xrightarrow{\text{a}} P \quad \text{Inde: } P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P' \quad Q(\tilde{y}) \xrightarrow{\theta} P', \quad Q(\tilde{z}) = P \]

\[ \text{Par}_0 : \quad P \xrightarrow{\theta} P', \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P', \quad \text{bn}(\ell(\theta)) \cap \text{fn}(Q) = \emptyset \]

\[ \text{Par}_1 : \quad P \xrightarrow{\theta} P', \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P', \quad \text{bn}(\ell(\theta)) \cap \text{fn}(Q) = \emptyset \]

\[ \text{Res} : \quad P \xrightarrow{\theta} P', \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P', \quad x \not\in \text{n}(\ell(\theta)) \]

\[ \text{Open} : \quad P \xrightarrow{\theta} P', \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P', \quad x \neq y \]

\[ \text{Com}_0 : \quad P \xrightarrow{\theta} P', Q \xrightarrow{\sigma z(w)} Q' \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P'[Q', y/w] \]

\[ \text{Close}_0 : \quad P \xrightarrow{\theta} P', Q \xrightarrow{\sigma z(w)} Q' \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P'[Q', y/w] \]

Just to show how enhanced labels are inductively built while deducing transitions, consider the process

\[ (\nu x)(\pi x.P_0 + \tilde{b}y.P_1 | P_2) + P_3. \]

The derivation of the output of \( x \) on channel \( a \) starting from the axiom is

\[ \xrightarrow{\theta} P' \quad P \xrightarrow{\theta} P' \quad P[\tilde{y}/\tilde{z}] \xrightarrow{\theta} P', \quad \text{Par}_0 \]

\[ (\nu x)(\pi x.P_0 + \tilde{b}y.P_1 | P_2) \xrightarrow{\theta} P_0 | P_2, \quad \text{Open} \]

Hereafter, we write a transition as \( P \xrightarrow{\theta} Q \) only if it is deductible according to the inference rules in Tab. 1; furthermore, we simply write it as \( \theta \), when it is unambiguous.

\textbf{Definition 2.3.} A proved transition system is a quadruple \((\mathcal{P}, \Theta, \xrightarrow{\theta}, P_0)\), where \( \mathcal{P} \) is the set of states (processes), \( \Theta \) is the labelling alphabet, \( \xrightarrow{\theta} \) is the transition relation defined in Tab. 1, and \( P_0 \in \mathcal{P} \) is the initial state.
Standard semantics of the \(\pi\)-calculus is obtained by relabelling each transition shown in Tab. 1 by using function \(\ell\) in Def. 2.2.

We now define proved computations.

**Definition 2.4.** If \(P_0 \xrightarrow{\theta} P_1\) is a transition, then \(P_0\) is the **source** of the transition and \(P_1\) is its **target**. A **proved computation** of \(P_0\) is a sequence of transitions \(P_0 \xrightarrow{\theta_1} P_1 \xrightarrow{\theta_2} \ldots\) such that the target of any transition is the source of the next one. We let \(\xi, \xi'\) range over proved computations. The notions of source and target are extended to computations.

3. STOCHASTIC SEMANTICS

We now show how to derive a probabilistic distribution \(F\) from a \(\theta\) label. The intended meaning of \(F\) is the cost of execution (duration) of the action \(\mu = \ell(\theta)\). The actual cost of \(\mu\) depends on the basic operations that the run-time support of the target architecture performs for firing \(\mu\). For example, the resolution of a choice imposes various operations on the target architecture such as checking the ready list or implementing fairness policies. An action fired after a choice costs more than the same action occurring deterministically. The other operations of our calculus reflect analogous routines of the run-time support and delay the execution of an action as well. Therefore, we first assign a cost to the transition corresponding to \(\mu\) on a dedicated architecture that only has to perform \(\mu\). We then model the performance degradation due to the run-time support by introducing a scaling factor for any routine implementing the transition. The new semantics takes into account the target architecture on which a system is run.

We derive the distributions of transitions by inspecting the syntactical contexts into which the actions which originate them are plugged. In fact, the context in which a \(\mu\) action occurs represents the operations that the target machine performs for firing \(\mu\) just because the structural operational semantics of a language specifies its abstract machine in a syntax-driven logical style. Accordingly, a linearization of a transition deduction (a proof term \(\theta\)) represents the execution of the corresponding run-time support routines on the target machine.

For instance, look again at the sample deduction \(\theta = +_0||_0 +_0 \mathcal{P}(x)\) reported at the end of the previous section. The enhanced label expresses that the abstract machine resolves two choices in favour of the left alternatives, thus adding extra costs to the output operation. Similarly, the selection of the left component of the parallel composition will have a cost depending on the allocation of processes and scheduling policies. The bound output means that the abstract machine has to handle the data structure representing the process environment in order to export the name \(x\) which is required to be fresh.

The tight connection of our cost model to the program syntax is a design choice. In fact, the way programs are written influences their performance. Consider two programs that only differ in some superfluous assignments or irrelevant loops. An example in our framework could be a \(P\) process that does not contain the name \(x\) and the \((\nu x)P\) process. A check on the name \(x\) is performed by the run-time support in the second process although \(x\) does not occur in \(P\) so that the two processes are
behavioral equivalent, but $(\nu x)P$ is slower than $P$. To further support our design choice, we recall that context-free performance prediction can produce results that are inadequate an order of magnitude.

Following what is discussed above, we assign a cost to each inference rule of the operational semantics via a $\$\$ function. In other words, the occurrence of a transition receives a duration time computed according to its deduction. The $\$\$ function encodes the delay that the abstract machine adds to the execution of an action in order to handle the data structures of the run-time support of the language. Of course, the nearer the abstract machine to the target architecture, the more accurate the prediction of execution costs will be. Note that our approach allows us to estimate the performance of the same program on different architectures simply by changing the cost function. The classical comparison of different programs (but equivalent as far as functionalities are concerned) on the same architecture is possible as well by fixing a unique $\$\$ for all of them.

There is no need to fix a $\$\$ function here, and we let it be a parameter of the definition of our model. For the sake of simplicity, we assume that $\$\$_o(\mu) = F_\mu \in \mathcal{F}$ (hereafter, we use $\mathcal{F}$ to denote a set of continuous probabilistic distribution functions) and that the slow-down factor is $\$\$_o(\vartheta) = r \in [1, +\infty)$. $\$\$\_o can be defined by inducing on the structure of $\vartheta$. For instance, we can sum the slow-down factors of any $o \in \vartheta$ as:

$$r = \$\$_o(\vartheta) = \sum_{o \in \vartheta} \$\$_o(o)$$

where

$$\$\$_o(||x||) = r_0, \$\$_o(+i) = r_1, \$\$_o((\nu x)) = r_2, \$\$_o(=m) = r_3, \$\$_o((y)) = r_4$$

where $r_i \in [1, +\infty)$, $i = 1, \ldots, 4$. Of course, $F_\mu$ and $r$ depend on architectural parameters as well. See [41, 40] for a complete definition of $\$\$\_o in the case of exponential distributions, and [10] for the description of an implementation.

We now consider synchronizations. The two partners perform independently several low-level operations locally to their environment in order to set up the structures they need to communicate. These operations correspond to the rules applied to satisfy the premises of the Com and Close rules, which are recorded by pairing the proof terms corresponding to the local operations of the partners. Afterwards, in order to pass through the context common to the two partners, a few operations are necessary. The cost of these additional operators is derived using $\$\$\_o. For instance, consider the process

$$R + (((\nu x)!(\overline{a}x + \overline{b}y)) | ((a(x) | b(x)) + Q))$$

The communication along link $a$ has the label $+1(||_0 +_0 a(x), ||_1 +_0 ||_0 a(x))$. The two components of the pair are the local operations of the partners, while the leftmost $+1$ is a common operation performed after the Close0 rule has been applied.

We then use the function $f_{||} : \mathcal{L}^* \times \mathcal{L}^* \to [1, +\infty)$ to take the distance of the two partners into account. For encoding locations, we use $\chi_0, \chi_1 \in ||_0, ||_1 : \mathcal{L}^{\ast} = \mathcal{L}^*$. To understand why, consider the binary abstract syntax tree of a process, where the parallel composition $|$ is the only syntactic operator. Then, a sequence $\chi$ is the
access path from the root (the whole process) to a leaf (a sub-process). Consider for instance \((P_0 \mid P_1) \mid (P_2 \mid P_3)\) and its syntax tree shown in Fig. 1. The access path \(\|_1\|_1\|_0\) from the root uniquely identifies the process \(P_3\), while \(\|_0\|_1\) is the path for \(P_1\). Therefore, the allocation of processes can be described by \(\text{All} : \mathcal{L}^* \to \text{Loc}\), where \(\text{Loc}\) is the set of physical locations. We do not explicitly introduce the function \(\text{All}\) here for the sake of presentation. Actually, \(\text{All}\) is only a degree of indirection from strings in \(\mathcal{L}^*\) (that hereafter by abuse of wording we call locations).

The two arguments of \(f_{\|}\), together with allocation tables, can be used to determine where the two communicating processes actually reside. Note that binary trees are only used to generate names of locations and they are completely independent of the topology of the interconnection network.

To apply function \(f_{\|}\), we need an auxiliary function \(\xi : (\mathcal{L} \cup \mathcal{O})^* \to \mathcal{L}^*\) that extracts the parallel tags from proof terms, inductively defined as \((\varepsilon\) is the empty string)\n
\[
\xi = \varepsilon, \quad \sigma\xi = \begin{cases} \|\sigma\| & \text{if } \sigma = \|; \\ \xi & \text{otherwise} \end{cases}
\]

The tags that we discard from enhanced labels only specify characteristics of sequential components of the system. Thus they are not relevant for allocation tables.

Hereafter, we use \(f\) for the density function corresponding to the distribution function \(F\) of a continuous random variable. Remember that the relation between density and distribution functions is \(\int_{-\infty}^{\infty} f(t) dt = F(\|)\), or equivalently \(F'(t) = f(t)\), where \(F'\) is the derivative of \(F\).

Function \(\$\) is defined by using the auxiliary functions \(\$_{\|}\) as the basis along with \(\$\) and \(f_{\|}\). To slow down the firing time of the transitions, we use a homotopy \(^2\) on the arguments of the distribution functions. In other words, given a function \(F(x)\), we define \(G(x) = F(x/t)\) with \(t \in \mathbb{R}^+\). When \(F\) is a distribution function, \(\lim_{x \to +\infty} F(x) = 1\) and the speed at which \(F\) approaches its asymptotic value 1.

---

\(^2\)Given a vector space \(V\) on \(\mathbb{R}\) and \(t \in \mathbb{R}, t > 0\), the function \(t I : V \to V\) with \(x \mapsto tx\) is a homotety. If \(V\) is equipped with a scalar product (e.g., \(\mathbb{R}^n\)), a homotety with \(t < 1\) \((t > 1)\) makes the distance between any two points in the space smaller (greater). By abuse of wording, sometimes the term homotety is used to refer to the constant \(t\), as well. In our setting, we use the constant \(t\) to tune the arguments of distribution functions and we still call the transformation a homotety.
makes the time interval described by a random variable $T$ with distribution $F$ vary. The faster $F$ approaches 1, the smaller the time interval, and hence the faster the transition corresponding to $T$. The homotety $x/t$ makes $G$ faster than $F$ when $t < 1$, and $G$ slower than $F$ when $t > 1$. This is why we let the codomain of $\$_a$ and $f_1$ be $[1, +\infty)$.

Note that one may resort to density functions $f(x)$ to slow-down transition speed. The idea is to increase the expectation of the time interval which is $EX_f = \int xf(x)dx$. We still apply the homotety $x/t$, yielding a function $f_t(x) = f(x/t)$. The expectation becomes

$$EX_{f_t} = \int xf_t(x)dx = t \int (x/t)f(x/t)dx/t = tEX_f.$$

This result agrees with the homotety applied to distribution functions because $t > 1$ increases the expectation and thus slows-down the corresponding transition.

We can now define our cost function $\$.$

**Definition 3.1.** Given a set $\mathcal{F}$ of continuous probabilistic distributions, the function $\$: $\Theta \to \mathcal{F}$ is defined as follows:

$$\$(\theta\mu) = F\left(\frac{x}{\$_a(\theta)}\right) \text{ if } \$_a(\mu) = F(x),$$

$$\$(\theta\alpha_0, \theta\alpha_1) = F\left(\frac{x}{\$_a(\theta) \bullet f_1(\alpha_0, \alpha_1)}\right) \text{ if } \min\{\$, \$\} = F(x)$$

where $\bullet : [1, +\infty) \times [1, +\infty) \to [1, +\infty)$ is monotonic and such that $x \bullet y \geq z$ with $z \in \{x, y\}$.

For instance, the sum and multiplication on $\mathcal{R}$ satisfy the requirements for $\bullet$.

Note that determining the distribution of synchronizations is a key point in distinguishing different proposals of stochastic process algebras. Here we demand its computation to function $\$$. This means that the distributions of synchronization vary according to the context into which they are plugged and to the architectures on which the partners run. We thus reduce the selection of distributions to the selection of suitable architectures and placement of processes. This way the designer may abstract from stochastic details and concentrate on the characteristics of the hardware. Examples of application of this mechanism can be found in [40, 10].

Since we are dealing with performance evaluation, we need to eliminate the nondeterminism introduced by the choice operator from stochastic transition systems. Hence, we introduce a race condition that selects the transition to be fired among the ones enabled in a state. All the enabled transitions attempt to proceed, but only the fastest one succeeds. This mechanism makes the nondeterministic choice a probabilistic one. Note that the continuous nature of probabilistic distributions ensures that the probability of two transitions ending simultaneously is 0. Moreover, as the duration of transitions is expressed by random variables, different transitions are selected on different attempts.

Hereafter the apparent rate of an action $a$ in $P$ (written $r_a(P)$) will be the rate captured by an external observer of the system, which can only register actions and their occurrence frequency (for a formal definition see the theorem below).
[30]. Also, $T_i$ denotes the random variable describing the time interval associated with a $P \xrightarrow{\theta_i} P_i$ transition. The following theorem shows how to compute useful probabilities and transition distributions.

**Theorem 3.1.** The probability of $P \xrightarrow{\theta_i} P_i$ is

$$p_i = \int_0^\infty f_i(t) \cdot \prod_{p_{ij} \neq P_i \atop i \neq j} (1 - \theta_j(t))dt;$$

the distribution of the random variable $T_i$ which describes the time interval associated with $P \xrightarrow{\theta_i} P_i$ is

$$\hat{F}_i(t) = \frac{\int_0^t f_i(x) \cdot \prod_{p_{ij} \neq P_i \atop i \neq j} (1 - \theta_j(x))dx}{p_i};$$

the apparent rate of an action in $P$ is

$$r_a(P) = \sum_{p_{ij} \neq P_i \atop \ell(\theta_i) = a} p_i;$$

the probability of $P \xrightarrow{\theta_i} P_i$, $\ell(\theta_i) = a$, given that an action occurred is

$$\frac{p_i}{r_a(P)}$$

**Proof.** By race condition, the probability that $P \xrightarrow{\theta_i} P_i$ occurs is $Pr(\bigwedge_{i \neq j} T_i < T_j)$. To compute this probability, consider the conditional probability distribution

$$F_{T_i|P_j} = Pr(\bigwedge_{p_{ij} \neq P_i \atop i \neq j} T_i < T_j \mid T_i = t) = Pr(\bigwedge_{p_{ij} \neq P_i \atop i \neq j} T_j > t \mid T_i = t) =$$

by independence of the variables $T_j$

$$Pr(\bigwedge_{p_{ij} \neq P_i \atop i \neq j} T_j > t) = \prod_{p_{ij} \neq P_i \atop i \neq j} (1 - \theta_j(t)).$$

Then, the probability of $P \xrightarrow{\theta_i} P_i$ is given by the continuous version of the theorem of total probability

$$\int_0^\infty f_i(t) \cdot \prod_{p_{ij} \neq P_i \atop i \neq j} (1 - \theta_j(t))dt = p_i.$$
Now consider the second statement. By definition of distribution function,

\[
\hat{F}_i(t) = \Pr(T_i \leq t \mid \bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j < T_i) = \int_0^t f_i(x) \cdot \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j < T_i \mid T_i \leq t) \, dx
\]

by the continuous analog of Bayes’ rule

\[
\frac{\int_0^t f_i(x) \cdot \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j < T_i \mid T_i \leq t) \, dx}{\int_0^\infty f_i(x) \cdot \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j < T_i \mid T_i \leq t) \, dx}.
\]

We can write \(\Pr(\bigwedge_{i \neq j} T_j < T_j \mid T_i \leq t)\) as \(\Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j > x)\), and by independence of the variables \(T_j\), we obtain

\[
\Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_j > x) = \prod_{p \neq j} \Pr(T_j > x) = \prod_{p \neq j} (1 - \delta(\theta_j)(x)),
\]

from which the thesis follows.

The apparent rate in the statement can be written as

\[
r_r(P) = \bigcup_{\theta \neq a} \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_i < T_j) = \sum_{p \neq j} \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_i < T_j).
\]

because \(\forall i \neq j \cdot \bigwedge_{p \neq j, \theta_j \neq \theta_i} T_i < T_j \cap \bigwedge_{p \neq j, \theta_j \neq \theta_i} T_i < T_j = \emptyset\)

\[
\sum_{\theta \neq a} \Pr(\bigwedge_{p \neq j, \theta_j \neq \theta_i} T_i < T_j) = \sum_{\theta \neq a} p_i.
\]

The conditional probability of the statement can be written as

\[
\Pr(\bigwedge_{p \neq j} T_i < T_j \mid \bigvee_{p \neq j} (\bigwedge_{p \neq j, \theta_j = \theta_i} T_h < T_j)) = \frac{\Pr(\bigwedge_{p \neq j} T_i < T_j \wedge \bigvee_{p \neq j, \theta_j = \theta_i} (\bigwedge_{p \neq j} T_h < T_j))}{\Pr(\bigvee_{p \neq j} (\bigwedge_{p \neq j, \theta_j = \theta_i} T_h < T_j))}.
\]

by definition of conditional probability

\[
\Pr(\bigwedge_{p \neq j} T_i < T_j \wedge \bigvee_{p \neq j, \theta_j = \theta_i} (\bigwedge_{p \neq j} T_h < T_j)) = \frac{\Pr(\bigwedge_{p \neq j} T_i < T_j \wedge \bigvee_{p \neq j, \theta_j = \theta_i} (\bigwedge_{p \neq j} T_h < T_j))}{\Pr(\bigvee_{p \neq j} (\bigwedge_{p \neq j, \theta_j = \theta_i} T_h < T_j))}.
\]
because \( T_i \) is associated with an \( a \)-transition and because the denominator is \( r_a(P) \),

\[
\frac{\Pr(\bigwedge_{\substack{p \xrightarrow{a,j} p_j \mid i \neq j}} T_i < T_j)}{r_a(P)} = \frac{p_i}{r_a(P)}
\]

To get performance measures from our transition systems, we must update the

To get performance measures from our transition systems, we must update the
distributions of the random variables that express the time interval associated with
distributions of the random variables that express the time interval associated with
transitions in correspondence with branching points. We also compute the occurrence
transitions in correspondence with branching points. We also compute the occurrence
probability for any transition and record it in the transition labels. The
probability for any transition and record it in the transition labels. The
first two statements of Theorem 3.1 allow us to compute the correct occurrence
first two statements of Theorem 3.1 allow us to compute the correct occurrence
probabilities and distributions. The new transition system is called stochastic.
probabilities and distributions. The new transition system is called stochastic.

**Definition 3.2.** The quadruple \( (P, \Theta \times \mathcal{F} \times [0..1], \rightarrow, P_0) \) is the **stochastic transition system** associated with process \( P_0 \), where the real in \([0..1]\) denotes transition occurrence probability. The relation \( \rightarrow \) is defined as

\[
\frac{P \xrightarrow{\theta} P_i}{P \xrightarrow{\theta, \tilde{P}_i, \tilde{p}_i} P_i}
\]

where

\[
\tilde{p}_i = \frac{\int_0^t f_i(x) \cdot \prod_{p \xrightarrow{a,j} p_j \mid i \neq j} (1 - s(\theta_j)(x)) \, dx}{\int_0^\infty f_i(x) \cdot \prod_{p \xrightarrow{a,j} p_j \mid i \neq j} (1 - s(\theta_j)(x)) \, dx}, \quad \text{and}
\]

\[
p_i = \int_0^\infty f_i(t) \cdot \prod_{p \xrightarrow{a,j} p_j \mid i \neq j} (1 - s(\theta_j)(t)) \, dt.
\]

The labels distinguish stochastic transitions from proved ones.

4. **ENABLING MEMORY DISCIPLINE**

We now introduce a relation of enabling between the transitions of a computation simply by looking at their labels [20]. This relation between transitions will be used in the next section to deal with general distributions when the random variables associated with the transitions of a computation are not independent. Hereafter we write \( \vartheta \) in place of \( \triangledown \) for the sake of readability. Also, we define the enabling relation on proved computations. Its extension to stochastic computations only amounts to applying the definitions to the first component of the stochastic transition labels. Consequently, enabling could be computed simultaneously with stochastic information. We prefer to present it as a further step simply to improve readability.

4.1. **Enabling and concurrency**

We first define structural dependencies. A transition labelled \( \vartheta \mu \) depends on a previous transition labelled \( \vartheta' \mu' \) if \( \vartheta' \) is a prefix of \( \vartheta \) (the tuning needed to cover
communications is explained below). The underlying idea is that the two transitions have been derived using the same initial set of rules and are thus nested in a prefix chain (or they are connected by communications in a similar way).

Definition 4.1. If \( P_0 \xrightarrow{\theta_0} P_1 \xrightarrow{\theta_1} \ldots \xrightarrow{\theta_n} P_{n+1} \) is a proved computation, and hereafter \( i, j \in \{0, 1\} \), then \( \theta_n \) has a direct structural dependency on \( \theta_h, h < n \), \((\theta_h \mathrel{\lessdot}^{1}_{str} \theta_n)\) iff

- \( \theta_h = \theta \mu, \theta_h = \varphi \mu' \) and \( \varphi' \) is a prefix of \( \varphi \); or
- \( \theta_h = \theta \mu, \theta_h = \varphi' (\theta_0 \mu_0, \theta_1 \mu_1) \) and \( \exists i : \varphi' \varphi_i = \) a prefix of \( \varphi \); or
- \( \theta_h = \theta (\theta_0 \mu_0, \theta_1 \mu_1), \theta_h = \varphi' \mu', \exists i : \varphi' = \) a prefix of \( \varphi \); or
- \( \theta_h = \theta (\theta_0 \mu_0, \theta_1 \mu_1), \theta_h = \varphi' (\theta_0 \mu_0, \theta_1 \mu_1) \), \( \exists i, j : \varphi' \varphi_j = \) a prefix of \( \varphi \).

The structural dependencies of \( \theta_n \) are obtained by reflexive and transitive closures of \( \lessdot^{1}_{str} \), i.e., \( \lessdot_{str} = (\lessdot^{1}_{str})^* \).

The last two items in Def. 4.1 say that a \( \theta \) transition enables a communication if it enables one of its components. Also, we need the transitive closure of \( \lessdot^{1}_{str} \) to implement the cross inheritance of the causes of the communication partners for the residual processes.

Consider the process

\[
P_0 = (\nu b)(a, \overline{b} | d.b.(\nu z)(\overline{x} \mid \overline{z}))
\]

and its proved computation (here only labelled with tags \( \| \); \( \nu b \)) which prefixes all labels is omitted

\[
P_0 \xrightarrow{\| \overline{a}} P_1 \xrightarrow{\| \overline{d}} P_2 \xrightarrow{\| \overline{\nu b} \overline{a}} P_3 \xrightarrow{\| \overline{\nu b} \overline{c}} P_4 \xrightarrow{\| \overline{\nu b} \overline{z}} (\nu b)(0) (0 | 0))
\]

(1)

Since \( \| \), the proof term of \( b \), is a prefix of the proof term \( \| \| \| \| \) of the bound output, \( \overline{x}(z) \) depends on the communication, thus it also inherits the causes of the sender (the first transition). The bound output \( \overline{x}(z) \) also depends on the second transition whose proof term is a prefix of its own.

The second step defines name dependencies that are only generated by bound outputs. This is because a name dependency between an input, which binds a name \( y \), and its following usage always induces a structural dependency as well (see [20] for more details).

Definition 4.2. If \( P_0 \xrightarrow{\theta_0} P_1 \xrightarrow{\theta_1} \ldots \xrightarrow{\theta_n} P_{n+1} \) is a proved computation, then the name enabler of \( \theta_n \), if any, is \( \theta_h \) \((\theta_h \mathrel{\lessdot}_{nam} \theta_n)\) such that \( \ell(\theta_h) = \overline{x}(a), \forall j, h < j < n, a \in b n(\ell(\theta_j)) \), and \( \ell(\theta_n) \in \{ \overline{x}(z), \overline{a}(z), \overline{x}(z) \} \).

Look again at computation (1). The output on link \( z \) depends on the bound output, as \( z \) has been extruded by \( \overline{x}(z) \).

All the dependencies of a transition are the union of its structural dependencies, its name dependency \( \theta_i \), and the set containing the name and the structural dependencies of \( \theta \). Thus the enabling relation is

\[
\lessdot = (\lessdot_{str} \cup \lessdot_{nam})^*.
\]
We also need the definition of a concurrency relation (\(\sim\)) between transitions that we recall from [20]. Roughly, two transitions are concurrent if they result from firing two prefixes lying on opposite sides of a \(|\) and there is no way of sequentializing them.

**Definition 4.3.** If \(P_1 \xrightarrow{\theta_0} P_1 \xrightarrow{\theta_1} \ldots \xrightarrow{\theta_n} P_{n+1}\) is a proved computation, then the concurrency relation between transitions is \(\sim\) such that \(\theta_h \sim \theta_n \Leftrightarrow \theta_h \not\approx \theta_n\).

The above definition allows us to form the following theorem, which is proven in [20].

**Theorem 4.1.** If \(\mathcal{C}[,\cdot,\cdot], \mathcal{C}'[,\cdot,\cdot], \mathcal{C}_0[,\cdot,\cdot]\) and \(\mathcal{C}_1[,\cdot,\cdot]\) are (non-empty) contexts with (exactly) two holes, then the proved transition system contains the diamond

\[
\begin{array}{c}
\mathcal{C}_0[P, \pi_1, Q] \\
\xrightarrow{\theta_0} \mathcal{C}_1[\pi_0, P, Q] \\
\mathcal{C}'[P, Q] \\
\xrightarrow{\theta_1} \mathcal{C}_0[\pi_1, P, Q]
\end{array}
\]

with actions \(\theta_0 (\theta_1)\) originated by the same prefix \(\pi_0 (\pi_1)\) if and only if \(\theta_0 \sim \theta_1\).

### 4.2. Distribution of transitions

We now use enabling to keep track of the history of a system to determine the firing distribution of transitions. Here we use the enabling memory discipline with race defined for stochastic Petri nets [1] and used in TIPP stochastic process algebra [24] (although implemented with a different mechanism; see below). The firing distribution of a transition accounts for the work performed by the corresponding action once it becomes enabled.

Consider for instance the process \(a|b\), and its computation

\[
a|b \xrightarrow{\|b\}^a} 0|b \xrightarrow{\|b\}^b} 0|0
\]

Since the transition \(a|b \xrightarrow{\|b\}^a} a|0\) is possible as well because \(\|a\|b\|\), and the selection of the one labelled \(a\) does not prevent \(b\) from occurring, the random variable describing the time interval \(T_0\) associated with the first transition is not independent on \(T_1\) associated with the second one. In fact, the time interval of the \(b\)-transition in the computation above overlaps with and continues after \(T_0\). Thus, according to the enabling memory discipline, the variable \(T_1\) must account for the time elapsed during the firing of \(a\), plus the extra-time up until the completion of \(b\).

In [1], the enabling memory discipline with race is implemented through so-called age variables associated with transitions. Instead, [24] modifies the syntax of the language (and hence its semantics) in order to keep track of the number of time
intervals during which a transition was enabled, but a concurrent one was selected
for firing. We show here that we do not need to modify the syntax of the π-calculus
or the states of its transition system to handle general distributions.

Let \( P_0, \theta_0, F_0, p_0 \rightarrow P_1, \theta_1, F_1, p_1 \rightarrow \ldots \rightarrow P_n, \theta_n, F_n, p_n \rightarrow P_{n+1} \) be a stochastic computation, and
assume that one wants to determine the firing distribution of \( \theta_n \). Since mutual
exclusive (or conflicting) transitions are represented by branching points in the
structure of transition systems, any pair of transitions in a given computation is
either in an enabling or in a concurrency relation (see Def. 4.3 and also [20]).
Therefore, we only need to find the maximum \( i \) \( (0 \leq i < n) \), if any, such that
\( \theta_i \leq \theta_n \). Then, all the transitions following \( \theta_i \) and preceding \( \theta_n \) are concurrent
with \( \theta_n \). (Note that there is at least one such transition if \( i < n - 1 \).) All the time
periods in which these transitions occurred must influence the firing distribution of
\( \theta_n \). We first need an auxiliary definition of immediate dependency. A transition \( \theta_i \)
immediately enables \( \theta_n \) if there is no transition between \( \theta_i \) and \( \theta_n \) that enables \( \theta_n \).
We denote the new relation \( \leq_c \) because it is the covering relation of \( \leq \).

**Definition 4.4.** If \( P_0, \theta_0, F_0, p_0 \rightarrow P_1, \theta_1, F_1, p_1 \rightarrow \ldots \rightarrow P_n, \theta_n, F_n, p_n \rightarrow P_{n+1} \) is a stochastic
computation, then \( \theta_i \) immediately enables \( \theta_n \) \( (\theta_i \leq_c \theta_n) \) iff \( \theta_i \leq \theta_n \), and \( \forall j, i < j < n, \theta_j \leq \theta_n \).

Note that the new relation \( \leq_c \) only differs from \( \leq_{str}^1 \) because the latter relation
can select transitions which are not the immediate enablers of the current one. For instance,
consider computation (1) again. It is \( ||d \leq_{str}^1 ||d ||\pi(z) \), but
\( ||d \leq_c ||d ||\pi(z) \).

We can now define the distribution of the random variable \( T_n \) associated with
\( \theta_n \).

**Definition 4.5.** If \( P_0, \theta_0, F_0, p_0 \rightarrow P_1, \theta_1, F_1, p_1 \rightarrow \ldots \rightarrow P_n, \theta_n, F_n, p_n \rightarrow P_{n+1} \) is a stochastic
computation, then the distribution of \( T_n \) is

\[
\Pr(T_n \leq t + \sum_{h=t+1}^{n-1} T_h \mid T_n > \sum_{h=t+1}^{n-1} T_h) \quad \text{with} \quad \theta_i \leq_c \theta_n
\]

assuming as usual that \( \sum_0 T_h = 0 \).

As described in [20], many semantic models (causal, local, interleaving) suitable
for behavioral analysis can be retrieved from the proved transition system of π-
calculus through simple relabelling functions of transition labels. Here we apply
the same idea to yield a transition system suitable for performance analysis by
relabelling stochastic computations.

We apply the relabelling function to transition \( \theta_n \) only after relabelling transitions \( \theta_i \), and \( 0 \leq i < n \). This is necessary to correctly compute the distribution
of \( \sum_{h=t+1}^{n-1} T_h \). We can thus inductively relabel any transition of a stochastic com-
putation by replacing the distribution of the transition with the one computed
according to Def. 4.5. Once again, note that the distributions of transitions can be
directly computed while building the stochastic transition system simply by com-
posing what follows with the calculations described in Def. 3.2. We think that this separation of concerns can help to understand or make things clearer.

**Definition 4.6.** If \( \xi_0 = P_0 \xrightarrow{\theta_0,F_0,p_0} P_1 \xrightarrow{\theta_1,F_1,p_1} \ldots \xrightarrow{\theta_{n-1},F_{n-1},p_{n-1}} P_{n+1} \) is a stochastic computation, the corresponding **performance computation** is

\[
\xi_{n+1} = P_0 \xrightarrow{\theta_0,F'_0} P_1 \xrightarrow{\theta_1,F'_1} \ldots \xrightarrow{\theta_{n},F'_n} P_{n+1}
\]

and is obtained by applying the function \( S_n \circ S_{n-1} \circ \ldots \circ S_0 \) to \( \xi_0 \) with

\[
S_i(\xi_i) = \xi_{i-1} \left\{ \left( P_i \xrightarrow{\theta_i,F'_i} P_{i+1} \right) \middle\vert \left( P_i \xrightarrow{\theta_i,F_i} P_{i+1} \right) \right\}
\]

where \( F'_i = \Pr(T_i \leq t + \sum_{h=j+1}^{i-1} T_h \mid T_i > \sum_{h=j+1}^{i-1} T_h), j < h < i, \theta_j \preceq \theta_i \).

### 4.3. Stochastic processes

In this subsection we show how to raise the relabelling of stochastic transitions from computations to stochastic transition systems.

The second firing of the same transition in a computation can be interpreted as a re-sampling of an experiment. Of course, two distinct experiments must be done independently of one another to be meaningful. In fact, under the firing policy of race with enabling memory, a new delay \( \emptyset \) has to be sampled if a disabled transition becomes re-enabled (see also [1]). Consequently, the history of the system that leads to a \( P \xrightarrow{\theta,F,p} P' \) transition must not be taken into consideration to compute the distributions of its following occurrence.

We first need an auxiliary definition to identify the computations whose transitions occur once at the most, and their source state is the initial state of the transition system.

**Definition 4.7.** If \( ts = \langle P, \Theta \times F \times [0..1] \rightarrow, P_0 \rangle \) is a stochastic transition system, and \( P_n \) one of its states, then the set of the **acyclic computations** from \( P_0 \) to \( P_n \) is

\[
AC(ts, P_n) = \{ \xi_i \mid \text{source}(\xi_i) = P_0, \text{target}(\xi_i) = P_n, P_n \xrightarrow{\theta_n,F_n,p_n} P_{n+1} \notin \xi_i, \\
\forall P_j \xrightarrow{\theta_j,F_j,p_j} P_{j+1}, \exists P_k \xrightarrow{\theta_k,F_k,p_k} P_{k+1} \in \xi_i, \\
j \neq k \Rightarrow P_j \xrightarrow{\theta_j,F_j,p_j} P_{j+1} \neq P_k \xrightarrow{\theta_k,F_k,p_k} P_{k+1} \}
\]

The following theorem establishes that a finite state transition system (that may have loops) gives origin to a finite set of finite acyclic computations.

**Theorem 4.2.** If \( ts = \langle P, \Theta \times F \times [0..1] \rightarrow, P_0 \rangle \) is a finite state stochastic transition system, then

\[
\forall P \in ts. AC(ts, P) \text{ is finite, and } \forall \xi \in AC(ts, P), \xi \text{ is finite.}
\]
Proof. Since the proved transition system is finite branching (see the rules in Tab. 1), the stochastic transition system is finite branching as well. In fact, we define it by relabelling proved transitions. Hence, a finite state transition system has a finite number of transitions. So they are the combination of its transitions as well as the length of its acyclic computations. □

Hereafter, we use \( \Pr(\xi) \) to denote the occurrence probability of the last transition of \( \xi \), i.e.,

\[
\Pr(\xi) = P_0 \frac{\theta_n F_0 P_0}{P_1 \frac{\theta_1 F_1 P_1}{\ldots \frac{\theta_n F_n P_n}{P_{n+1}}}} = \prod_{i=0}^{n} P_i.
\]

To compute the distribution of a \( P_n \frac{\theta_n F_n P_n}{P_{n+1}} \) transition under the firing policy of race with enabling memory, we rely on the set \( AC(ts, P_n) \). We apply Def. 4.6 to \( \xi_i \frac{\theta_n F_n P_n}{P_{n+1}} \) for any \( \xi_i \in AC(ts, P_n) \), which yields \( F^i_n \) as distribution for \( \theta_n \). We eventually obtain the distribution of \( \theta_n \) under the enabling memory discipline by mediating the \( F^i_n \)'s through the occurrence probabilities of \( \theta_n \) as a last transition of the computations in \( AC(ts, P_n) \).

**Definition 4.8.** If \( ts = \langle P, \Theta \times F \times [0.1], \rightarrow, P \rangle \) is a stochastic transition system, the corresponding performance transition system \( \langle P, A \cup \{ \tau \} \times F, \rightarrow, P \rangle \) is obtained by relabelling any transition \( P_n \frac{\theta_n F_n P_n}{P_{n+1}} \) as \( P_n \frac{\theta_n F_n P_n}{P_{n+1}} \) where

\[
F^i_n = P_n \times \sum_{\xi_i \in AC(ts, P_n)} \Pr(\xi_i) \times F^i_n
\]

with \( F^i_n \) as the distribution associated with \( P_n \frac{\theta_n F_n P_n}{P_{n+1}} \), by applying Def. 4.6 to \( \xi_i \frac{\theta_n F_n P_n}{P_{n+1}} \).

Note that the above definition is effective for finite state transition systems according to Theorem 4.2. Furthermore, performance transition systems can be inductively derived from processes without relying on stochastic transition systems (see the discussion immediately before Def. 4.6; the idea is to build the transition system from a breadth-first strategy and treat the generation of all the transitions exiting a state as atomic).

The enabling memory discipline as defined in this section, though it coincides with some proposals in the literature [1, 24], has certain limitations. The next section introduces a refined discipline.

5. REFINING THE ENABLING MEMORY DISCIPLINE

As announced in the Introduction, here we use a different notion of timer associated with transitions. We are not only interested in the CPU consumption of transitions, but rather in their response time. Therefore, we let our timers count the time during which transitions are enabled and not scheduled on a CPU as well.

Consider the proved computation again

\[
a | b \xrightarrow{1|a} 0 | b \xrightarrow{1|b} 0 | 0.
\]
The random variables $T_0$ and $T_1$ associated with $||a||$ and $||b||$ are considered dependent in Sect. 4.2 because the time period of $||b||$ overlaps with that of $||a||$. The motivation was that $||a||$ and $||b||$ are concurrent transitions, thus their execution ordering is irrelevant from a behavioral point of view. This is certainly true when we run the system on a single processor. Hence, concurrency is simulated by interleaving concurrent transitions and the dependency of these variables shows up.

Now consider a network of at least two machines and run $a||b$ on it. A suitable allocation of sub-processes permits a truly concurrent execution of $||a||$ and $||b||$ that can be represented by the transition $a||b \xrightarrow{||a||,||b||} 0[0]$. In this case, the dependency of the random variables $T_0$ and $T_1$ is no longer valid. In fact, the two transitions are executed by different and independent machines. Thus it is evident that the number of available resources influences the stochastic structure of the system at hand. We can generalize the dual machine network to any number of nodes without modifying our discussion. We only need to resort to transitions that carry up to $n$ enhanced labels.

Note that communications impose synchronization points between independent threads of computation. Consider for instance the system $(\nu c)(a,c,d,b,\bar{c}e)$ where the communication over $c$ imposes a synchronization between the concurrent executions of $a$ with $b$ and of $d$ with $e$. This synchronization works independently of the number of processors and therefore it is imposed by the structure of the system.

Given the operational semantics of the $\pi$-calculus, we can discuss how to generate transitions with multiple labels. We only need to label those transitions carrying a single $\theta$ with a singleton. Given a set of labels $I$, we write $\theta \in I$ for the more precise, yet verbose, $(\theta,F,p) \in I$. To improve readability, we write $\iota(\theta)$ for the distribution $F$ associated with $\theta$ in the labels of performance computations.

**Definition 5.1.** Assuming that standard labels are actually singletons, the following rule composes transitions labelled by sets of actions to yield higher-dimension transitions

\[
P \xrightarrow{I_0} P', P' \xrightarrow{I_1} Q, I_0 \sim I_1 \quad \frac{P \xrightarrow{I_0 \cup I_1} Q}{P \xrightarrow{I_0 \cup I_1} Q}, \quad |I_0 \cup I_1| \leq n
\]

where $n$ is the number of processors available, $|I|$ the cardinality of the set $I$, and $I_0$ and $I_1$ sets of labels with

\[
I_0 \sim I_1 \iff \forall \theta_0 \in I_0, \forall \theta_1 \in I_1, \theta_0 \sim \theta_1.
\]

Of course, the above definition can be applied to stochastic and performance transitions as well. The same strategy used to generate performance transition systems from processes applies here to generate higher-dimension transition systems as well as their stochastic and performance versions.

As an example, consider the computation (1) again which, by allowing higher dimension transitions, becomes

\[
P_0 \xrightarrow{(||a||,||d||)} P_2 \xrightarrow{(||a||,||b||)} P_3 \xrightarrow{(||a||,||\bar{c}e||)} P_3 \xrightarrow{(||b||,||\bar{c}e||)} P_3 \xrightarrow{(||b||,||\bar{c}e||)} P_6
\]
We now modify Def. 4.6 to compute the distributions of the higher dimension transitions. Consider the higher dimension stochastic computation \( \xi \)

\[
P_0 \xrightarrow{I_0} P_1 \xrightarrow{I_1} \ldots \xrightarrow{I_n} P_{n+1}
\]

and assume that one wants to determine the firing distribution of \( \theta' \in I_n \). According to the enabling memory discipline, we must look for a \( \theta \in I_i \) with \( \theta \preceq_c \theta' \). Then, the activities belonging to any \( I_i \), where \( i < l < n \), are all concurrent with \( \theta' \). However, we do not need to consider the time elapsed for all the activities in \( I_l \) to compute the distribution of \( \theta' \). For any set \( I_l \), we only need to consider the slowest activity. Since all \( \theta \)'s in \( I_l \) are executed independently, the time period of the slowest one is given as

\[
\Pi_{\theta \in I_l} (1 - \iota(\theta)(x)).
\]

Note that this is a simplification. Indeed, the execution of \( \theta' \) can partially overlap with the one with the slowest activity in \( I_l \), if it does not enable \( \theta' \). For instance, consider \( a, b|c.d|e \) and its higher dimension computation

\[
a, b|c.d|e \xrightarrow{\{a, c, e\}} \xrightarrow{\{b, d\}} 0|0|0.
\]

The execution of \( d \) in the second transition can overlap with that of \( a \), if \( a \) is much slower than \( c \). What we get with our assumption is actually an upper bound to the response time of the system. Finally, note that this assumption can be used to work with synchronous systems as well.

**Definition 5.2.** If \( P_0 \xrightarrow{I_0} P_1 \xrightarrow{I_1} \ldots \xrightarrow{I_n} P_{n+1} \) is a higher dimension stochastic computation, then the distribution of the random variable \( T' \) associated with \( \theta' \in I_n \) is

\[
\Pr(T' \leq t + \sum_{h=i+1}^{n-1} \tilde{T}_h \mid \tilde{T}_h \text{ has distribution } \Pi_{\theta \in I_l} (1 - \iota(\theta)(x)) \text{ and } T' > \sum_{h=i+1}^{n-1} \tilde{T}_h)
\]

where \( \theta \in I_l, \theta \preceq_c \theta' \).

We can now adapt Def. 4.6 to higher dimension transitions. We only need to change the definition of \( S_i(\xi_i) \).

**Definition 5.3.** If \( \xi_0 = P_0 \xrightarrow{I_0} P_1 \xrightarrow{I_1} \ldots \xrightarrow{I_n} P_{n+1} \) is a higher dimension stochastic computation, the corresponding higher dimension performance computation \( \xi_{n+1} = P_0 \xrightarrow{I'_0} P_1 \xrightarrow{I'_1} \ldots \xrightarrow{I'_{n+1}} P_{n+1} \) is obtained by applying the function \( S_n \circ S_{n-1} \circ \ldots \circ S_0 \) to \( \xi_0 \) where

\[
S_i(\xi_i) = \xi_{i-1} \{(P_i \xrightarrow{I'_i} P_{i+1}) / (P_i \xrightarrow{I_i} P_{i+1}) \}
\]

where \( I'_i = \{\theta_j, F'_j \mid \theta_j \in I_i \} \) and \( F'_j \) is defined according to Def. 5.2.
5.1. Unbound processors

Here we study the cases where an unbound number of processors is available. We call this hypothesis maximal parallelism assumption. The weaker assumption of having a number of processors greater than or equal to the maximum number of simultaneously enabled transitions works as well. We can further weaken the assumption by assuming as many processors as the cardinality of the greater subset of enabled transitions such that no two transitions in the set are conflicting. This set identifies the maximal number of transitions that can be executed simultaneously and independently.

We now report a property of higher dimension transition systems (we omit the distributions of transitions in the labels). We write \( \rightarrow^* \) for the reflexive and transitive closures of a transition relation \( \rightarrow \).

**Proposition 5.1.** Given a \( P_0 \xrightarrow{\{\theta_1, \ldots, \theta_n\}} P_{n+1} \) transition in a higher dimension transition system, there are \( n! \) computations \( P_0 \rightarrow^* P_{n+1} \) whose transitions are labelled by the \( n! \) permutations of the \( \{\theta_1, \ldots, \theta_n\} \) singletons.

**Proof.** From \( P_0 \xrightarrow{\{\theta_1, \ldots, \theta_n\}} P_{n+1} \) we obtain \( P_0 \xrightarrow{\{\theta_1\}} P_1 \xrightarrow{\{\theta_2\}} \cdots \xrightarrow{\{\theta_n\}} P_{n+1} \) by repeated decompositions of the premises of the rule in Def. 5.1. Then, we apply Theorem 4.1 to any pair of consecutive concurrent transitions for as long as possible. Since any pair of enhanced labels in \( \{\theta_1, \ldots, \theta_n\} \) describes concurrent transitions, we can build the \( n! \) computations of the statement exactly right. \( \blacksquare \)

Actually, we have many more computations leading from \( P_0 \) to \( P_{n+1} \) under the assumptions of the above proposition. This depends on the decompositions that we can choose for the set \( \{\theta_1, \ldots, \theta_n\} \). It is possible to consider sets with \( 2, \ldots, n-1 \) elements and all their combinations such that the cardinality of the decompositions along with a computation from \( P_0 \) to \( P_{n+1} \) adds up to \( n \). We can then apply Theorem 4.1 generalized to higher dimension transitions to this computations. This discussion and Proposition 5.1 allows us to state the following theorem.

**Theorem 5.1.** Given a \( P_0 \xrightarrow{\{\theta_1, \ldots, \theta_n\}} P_{n+1} \) transition in a higher dimension transition system, there are

\[
\sum_{h=1}^{n} \binom{n}{h} \sum_{i} \binom{n-h}{i}
\]

computations leading from \( P_0 \) to \( P_{n+1} \) whose transitions are labelled by subsets of \( \{\theta_1, \ldots, \theta_n\} \) and for any computation \( P_0 \rightarrow^* P_{n+1} \); its transitions are labelled by \( I_1, \ldots, I_k \) \((k \leq n)\) with \( \sum_{i=1}^{n} |I_i| = n \), \( \bigcap_{i=1}^{k} I_i = 0 \) and \( \bigcup_{i=1}^{k} I_i = \{\theta_1, \ldots, \theta_n\} \).

This theorem is a generalization of the classical result of the permutation of concurrent transitions. The number of computations in the theorem above is obtained by simple combinatorial reasoning. The empty intersection derives from the irreflexivity of the concurrency relation.
We want to avoid all the computations that originate from generalized permutations of concurrent sets of transitions (see Def. 5.1) to satisfy the maximal parallelism assumption.

**Definition 5.4.** A maximal parallelism transition system is an higher dimension transition system \(ts\) generated according to the rule in Def. 5.1 and such that

- \(\forall P \xrightarrow{I_0} P' \in ts\), there is no \(P_0, \ldots, P_{n+1} \in ts\), \(P_0 \xrightarrow{I_0} \ldots \xrightarrow{I_n} P_{n+1}\) with \(P_0 = P\), \(P_{n+1} = P'\), and \(\bigcup_{i=0}^{n} I_i = I\).

A property of maximal parallelism transition systems is that their branching structure is only caused by nondeterministic choices. More formally, we have the following proposition.

**Proposition 5.2.** If \(P \xrightarrow{I_0} P_0\) and \(P \xrightarrow{I_1} P_1\) are two transitions of a maximal parallelism transition system, then \(I_0 \not\sim I_1\). More precisely,

\[\exists \theta_i \in I_0, \theta_j \in I_1 : \theta_i \not\sim \theta_j.\]

**Proof.** By contradiction. Assume that \(I_0 \sim I_1\). By a generalization of Theorem 4.1, there is \(P'\) such that \(P_0 \xrightarrow{I_1} P'\) and \(P_1 \xrightarrow{I_0} P'\). We can now apply the rule in Def. 5.1 to derive the transition \(P \xrightarrow{I_0 \cup I_1} P'\) against the condition stated in Def. 5.4. ■

The maximal parallelism assumption allows one to simultaneously fire all the transitions enabled in a given state. Therefore, the notion of enabling is useless because the activity enabling the current transition is always fired by the transition immediately preceding it. More formally, we have the following proposition.

**Proposition 5.3.** If \(P_0 \xrightarrow{I_0} P_1 \xrightarrow{I_1} \ldots \xrightarrow{I_{n+1}} P_{n+1}\) is a higher dimension computation, then, under the maximal parallelism assumption,

\[\forall \theta \in I_i, \exists \theta' \in I_{i-1} : \theta' \leq \theta\]

where \(0 < i \leq n\). In other words, the enabling relation between the transitions of a computation coincides with the temporal ordering of the transitions.

**Proof.** By contradiction. Assume that \(\forall \theta' \in I_{i-1} : \theta' \sim \theta, \theta \in I_i\). Then, according to the rule in Def. 5.1, in the higher dimension transition under the maximal parallelism assumption, \(P_i\) exists such that \(P_i \xrightarrow{\{\theta\}} P'_i \xrightarrow{I_i} P_{i+1}\) with \(\{\theta\} \cup I_i = I_i\). Furthermore, by applying the generalization to higher dimension transitions specified in Theorem 4.1 we can deduce that \(P_i \xrightarrow{\{\theta\}} P' \xrightarrow{I_i} P'_i\) and \(P_{i-1} \xrightarrow{I_i} P'_i\). Now, Def. 5.1 suffices to derive the transition \(P_{i-1} \xrightarrow{\{\theta\} \cup I_i} P'_i\), against the maximal parallelism assumption of the computation in the statement. ■
As a consequence of the above proposition, the sum $\sum_{h=0}^{n-1} \tilde{r}_h$ in Def. 5.2 always reduces to zero. The distribution of the $\theta$ activity is then $P(T' \leq t | T' > 0)$ and it turns out to be $\rho(\theta')$. This discussion allows us to state the following theorem.

**Theorem 5.2.** Under the maximal parallelism assumption, the enabling memory discipline reduces to temporal ordering discipline; i.e., the distribution in Def. 5.2 reduces to $\rho(\theta')$.

The above theorem states that the enabling memory discipline is helpful only when the resources of the system are limited; that is, enabling is needed when concurrent transitions are sequentialized in some order due to a lack of resources (e.g. processors). An immediate corollary follows.

**Corollary 5.1.** Any continuous distribution computed according to the enabling memory discipline enjoys the memory-less property under the maximal parallelism assumption.

The above corollary holds only because the history of the system is condensed to the transition that immediately precedes it. In other words, a transition is fired as soon as it becomes enabled.

### 6. PERFORMANCE BISIMULATION

In this section we extend the notion of late bisimulation of the $\pi$-calculus to cope with transition distributions. We call the new bisimulation *performance bisimulation*. We follow the approach introduced in [33] for CCS and arranged for PEPA in [30] and for TIPP in [28]. Since we relabelled the computations of our system with the distributions updated to consider both the branching structure and the history of the system, we simply need to compare the labels when checking bisimulation. This is the same idea adopted in [20] to define non-interleaving bisimulations for a qualitative analysis of systems. The uniform framework makes the integration of the analysis of qualitative and quantitative properties easy.

We must first recall the definition of parametric late bisimulation [20]. To determine the labels of transitions to be compared, we rely on a relabelling function that may inspect all the previous computation steps. Therefore our bisimulation will relate pairs $\langle P, \xi \rangle$, where $P$ is the target state of the computation $\xi$. ³ We now adapt the definition of parametric bisimulation to performance transition systems.

**Definition 6.1.** Given a relabelling function $f$, a binary relation $\mathcal{S}$ on pairs $\langle P, \xi \rangle$ of processes and performance computations is a *late $f$-simulation* if $\langle P, \xi \rangle \mathcal{S} \langle Q, \xi' \rangle$ implies that

- If $P \xrightarrow{\theta, r} P'$ and $\ell(\theta)$ is $\tau$, $\pi z$ or $\pi(y)$ with $bn(\ell(\theta)) \notin \text{fn}(P, Q)$, then for some $Q'$, $\langle Q', \xi' \rangle \mathcal{S} \langle Q', \xi' \rangle$ and $\langle P', \xi \rangle \xrightarrow{\theta', r'} P'$. ³

³Although $\xi$ uniquely determines $P$, we prefer to explicitly write out the process for readability. Also recall that the empty computation of $P$ has $P$ both as a source and target state.
• if \( P \xrightarrow{\alpha P, \xi} P' \) with \( y \notin \text{fn}(P, Q) \), then for some \( Q', Q' \xrightarrow{\alpha' P', \xi'} Q' \) and for all \( w \in N \), \( \langle P' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} P' \{ w/y \} \rangle \in S \langle Q' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} Q' \{ w/y \} \rangle \).

The relation \( S \) is a late \( f \)-bisimulation if both \( S \) and \( S^{-1} \) are late \( f \)-simulations. \( P \) is late \( f \)-bisimilar to \( Q \) (written \( P \approx_f Q \)) if there exists a late \( f \)-bisimulation \( S \) such that \( \langle P, c \rangle S \langle Q, c \rangle \).

If we put \( f = \ell \) in the above definition, we recover the classical late bisimulation of the \( \pi \)-calculus [36].

The notion of \( f \)-bisimulation completely ignores the \( F \) component of the labels of performance transitions and thus it is only suitable to investigate the qualitative properties of processes. To cope with the quantitative information encoded in \( F \), we raise the conditions in Def. 6.1 on transitions between states to conditions on transitions between equivalence classes of states. This is implemented via the function \( \gamma_0 \) in the following proposition that provides an alternative characterization of \( \approx_f \) in the style of [33, 30, 28].

**Proposition 6.1.** Given a relabelling function \( f \), a binary relation \( S \) on pairs \( \langle P, \xi \rangle \) of processes and performance computations is a late \( f \)-bisimulation if

\[
\forall \theta, \ell(\theta) \in \{ \tau y, \tau (y), \tau, x(y) \} \colon \gamma_0(\langle P, \xi, \theta, C \rangle) = \gamma_0(\langle Q, \xi', \theta', C \rangle),
\]

\[
f(\theta) = f(\theta') \quad \text{and} \quad bn(\ell(\theta)) \notin \text{fn}(P, Q)
\]

where

\[
\gamma_0(\langle P, \xi, \theta, C \rangle) = \left\{ \begin{array}{ll}
1 & \text{if } \exists \langle P', \xi' \xrightarrow{\alpha P, \xi} P' \rangle \in C \cdot \ell(\theta) \in \{ \tau y, \tau (y), \tau \} \\
1 & \text{if } \forall w \in N, \exists \langle P' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} P' \{ w/y \} \rangle \in C \cdot \ell(\theta) = x(y) \\
0 & \text{otherwise}
\end{array} \right.
\]

**Proof.** Consider the case \( \ell(\theta) = x(y) \). According to Def. 6.1, \( \langle P, \xi \rangle S \langle Q, \xi' \rangle \) implies that whenever \( P \xrightarrow{\alpha P, \xi} P' \), there exists \( Q' \) such that \( Q \xrightarrow{\alpha' P', \xi'} Q' \) with \( f(\theta') = f(\theta) \) and \( \forall w \in N, \langle P' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} P' \{ w/y \} \rangle \in S \langle Q' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} Q' \{ w/y \} \rangle \). Consequently,

\[
\forall w \in N, \langle Q' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} Q' \{ w/y \} \rangle \in S \langle P' \{ w/y \}, \xi \xrightarrow{\alpha P, \xi} P' \{ w/y \} \rangle.
\]

By definition of \( \gamma_0 \) we can conclude that

\[
\gamma_0(\langle P, \xi, \theta, [P' \{ w/y \}, \xi \xrightarrow{\alpha P, \xi} P' \{ w/y \}] \rangle) = 1
\]

\[
= \gamma_0(\langle Q, \xi', \theta', [P' \{ w/y \}, \xi' \xrightarrow{\alpha' P', \xi'} P' \{ w/y \}] \rangle).
\]

Since we imposed \( f(\theta) = f(\theta') \), we proved that \( S \) is a late \( f \)-simulation. Repeating the above starting with \( Q \xrightarrow{\alpha' P', \xi'} Q' \), we can conclude that \( S^{-1} \) is a late \( f \)-simulation as well, and hence that \( S \) is a late \( f \)-bisimulation.

The cases \( \ell(\theta) \in \{ \tau y, \tau (y), \tau \} \) are simpler and similar. \( \blacksquare \)
We instantiate the late $f$-bisimulation with our structural enabling relation $\preceq_{str}$. The motivation is twofold. First, since we cope with general distributions, we feel it is natural to include in the definition of bisimulation the same notion of dependency used to correctly compute the distributions of performance transitions. Second, structural enabling allows us to state a congruence property for our equivalence relation that is missing for classical $\pi$-calculus late bisimulation (see [5]). We can now define an enabling relabelling function to instantiate the $f$ function in Def. 6.1.

**Definition 6.2.** Given a performance computation $\xi = P_0 \xrightarrow{\theta_0, F_0} P_1 \xrightarrow{\theta_1, F_1} \ldots \xrightarrow{\theta_n, F_n} P_n$, its associated enabling computation $Et(\xi)$ is derived by relabelling any transition $\theta_h, F_k$ as $et_k$, where

$$et_k = \begin{cases} 
\tau, F_k & \text{if } \ell(\theta_h) = \tau \\
\langle \ell(\theta_h), \{h \neq k|\theta_h \preceq_{str} \theta_h, \ell(\theta_h) \neq \tau\}\rangle, F_k & \text{otherwise}
\end{cases}$$

By abuse of notation we will sometimes write $Et(\theta_h)$ in place of $et_k$.

To introduce our performance bisimulation we also need to modify the definition of the function $\gamma_0$ in Proposition 6.1 in order to take the duration of transitions into account. (Remember that we write $T_i$ for the random variable, which describes the time interval of a $P \xrightarrow{\theta, F} P_i$ transition.)

**Definition 6.3.** A binary relation $\mathcal{S}$ on pairs $(P, \xi)$ of processes and performance computations is a **performance bisimulation** if $(P, \xi) \mathcal{S} (Q, \xi')$ implies that for any equivalence class $C$ originating from $\mathcal{S}$

$$\forall \theta, \ell(\theta) \in \{\mathcal{F}(y, x(y), \tau, x(y)) | \gamma((P, \xi), \theta, C) = \gamma((Q, \xi'), \theta', C),$$

$$Et(\theta) = Et(\theta') \text{ and } bn(\ell(\theta)) \notin fn(P, Q) \}$$

where

$$\gamma((P, \xi), \theta, C) = \begin{cases} 
\Pr(T_h \leq t | T_h = \min\{T_i\}, \exists P', \xi \xrightarrow{\theta, F} P' \in C . \\
\Pr(T\theta \leq t | T\theta = \min\{T_i\}, \forall w \in N, \\
\exists (P', \xi, \theta, w/y) | \xrightarrow{\theta, F} P' \{w/y\} \in C . \\
\Pr(P' \xrightarrow{\theta, F} P' \{w/y\}) \text{ otherwise}
\end{cases}$$

$P$ is performance bisimilar to $Q$ (written $P \approx_P Q$) if there is a performance bisimulation $\mathcal{S}$ such that $(P, \xi) \mathcal{S} (Q, \xi)$.

In the above definition we consider the maximum transition speed from one equivalence class to another via the *same* action label $\mu$ (indeed $Et(\theta) = Et(\theta')$ implies $\ell(\theta) = \ell(\theta')$). In other words, we compare two systems on their fastest runs. Hence, the usage of the min operator in the definition of $\gamma$.

---

4We can use the full enabling relation $\preceq$ without altering the following results. We prefer to rely on $\preceq_{str}$ to simplify the technical presentation.
An important issue in the definition of equivalences in the setting of stochastic process algebras concerns the compositional minimization of system descriptions. We prove a congruence result for our performance bisimulation below, following the same pattern used in [5] for their causal bisimulation. We start with some auxiliary definitions and lemmas.

**Definition 6.4.** A substitution \( \sigma : \mathcal{N} \rightarrow \mathcal{N} \) is \( \$_\alpha \)-preserving iff \( \sigma(x) = y \) implies that \( \$_\alpha(x) = \$_\alpha(y) \).

Hereafter we write \( \theta \sigma \) meaning \( \sigma \) applied to \( \ell(\theta) \) and assume any substitution as being \( \$_\alpha \)-preserving.

The following lemma shows how substitutions affect transitions.

**Lemma 6.1.** If \( \sigma \) is a \( \$_\alpha \)-preserving substitution and \( P \) a process, then

1. \( P \xrightarrow{\theta,F} P' \Rightarrow P\sigma \xrightarrow{\theta\sigma,F} P'\sigma, \ell(\theta) \neq \tau, Et(\theta) = Et(\theta\sigma) \);
2. \( P \xrightarrow{\theta,F} P' \Rightarrow P\sigma \xrightarrow{\theta,F} P'\sigma \);
3. \( P \xrightarrow{\theta,\{a_0,a_1\},F} P' \Rightarrow P\sigma \xrightarrow{\theta,\{a_0,a_1\},F} P'\sigma, Et(\theta_0) = Et(\theta_0\sigma), Et(\theta_1) = Et(\theta_1\sigma) \);

**Proof.** The proof is clear by noting that \( \sigma \) only affects the action names that are not considered at all by the definition of \( \leq_{st} \) (see Def. 4.1) and by applying the same result for standard late bisimulation [36].

We now use a simple proof technique developed in [36] and based on ground bisimilarity.

**Definition 6.5.** A binary relation \( \mathcal{S} \) on pairs \( \langle P, \xi \rangle \) of processes and performance computations is a ground performance bisimulation up to \( \equiv \) and restriction if \( \langle P, \xi \rangle \mathcal{S} \langle Q, \xi' \rangle \) implies that for any equivalence class \( C \) originating from \( \mathcal{S} \)

\[
\gamma'\langle (P, \xi), \theta, C \rangle = \gamma'\langle (Q, \xi'), \theta', C \rangle, Et(\theta) = Et(\theta') \text{ and } bn(\ell(\theta)) \notin \text{fu}(P, Q)
\]

where \( \gamma'\langle (P, \xi), \theta, C \rangle = \Pr(T_h \leq t \mid T_h = \min\{T_i\}, \exists (P', \xi \xrightarrow{\theta,F} P') \in C : P \xrightarrow{\theta,F} P' \) and \( \langle P', \xi \xrightarrow{\theta,F} P' \rangle, \langle Q', \xi \xrightarrow{\theta',F} Q' \rangle \in C \) and \( P' \equiv (\nu \tilde{b})P_1, Q' \equiv (\nu \tilde{b})Q_1. \)

\( P \) is ground performance bisimilar to \( Q \) (written \( P \approx_p^\mathcal{S} Q \)) if there is a ground performance bisimulation \( \mathcal{S} \) such that \( \langle P, c \rangle \mathcal{S} \langle Q, c \rangle \).

Standard concurrency theory [36] establishes the relation between ground and non ground bisimulations for the \( \pi \)-calculus.

**Lemma 6.2.** If \( \mathcal{S} \) is a ground performance bisimulation up to \( \equiv \) and restriction, then \( \mathcal{S} \subseteq \approx_p^\mathcal{S} \).

The theorem below states that ground performance bisimulation is preserved by substitutions.
Theorem 6.1. If $\sigma$ is a $S_\alpha$-preserving substitution, then $\langle P, \xi \rangle \approx_P^\ell \langle Q, \xi' \rangle$ implies $\langle P\sigma, \xi\sigma \rangle \approx_P^\ell \langle Q\sigma, \xi'\sigma \rangle$.

Proof. Mimicking [5], we show that

$$S = \{\langle P\sigma, \xi\sigma \rangle, \langle Q\sigma, \xi'\sigma \rangle | \langle P, \xi \rangle \approx_P^\ell \langle Q, \xi' \rangle \land \sigma \text{ is } S_\alpha\text{-preserving} \}$$

is a ground performance bisimulation up to $\equiv$ and restriction. For any $P\sigma \rhd_{\theta, P'} P'$ we have to find $P_1, Q_1, \tilde{b}, \sigma'$ such that $Q\sigma \rhd_{\theta', P'} Q'$ with $P' \equiv (\nu \tilde{b})P_1\sigma'$, $Q' \equiv E(\theta) = E(\theta')$ and $\gamma'(\langle P\sigma, \xi\sigma \rangle, \theta, C) = \gamma'(\langle Q\sigma, \xi'\sigma \rangle, \theta', C)$. Theorem 4.11 in [5] and Lemma 6.1 guarantee the first two conditions of the statement above. We only have to check the equality of the two $\gamma'$-functions. Since $S_\alpha$-preserving substitutions do not affect the duration of transitions (Lemma 6.1), and since $\langle P, \xi \rangle \approx_P^\ell \langle Q, \xi' \rangle$ implies $\gamma'(\langle P, \xi \rangle, \theta, C) = \gamma'(\langle Q, \xi' \rangle, \theta', C)$, we have proven the theorem. $
blacksquare$

Since to obtain congruences one has to expect that bisimilarity is preserved by substitutions, a corollary of Theorem 6.1 states a congruence result for $\approx_P^\ell$.

Corollary 6.1. $\approx_P^\ell$ is a congruence for the $\pi$-calculus without matching.

Eventually we prove that our performance bisimulation is indeed a congruence.

Theorem 6.2. $\approx_P$ is a congruence for the $\pi$-calculus without matching.

Proof. We only need to show that $\approx_P^\ell$ and $\approx_P$ coincide on the considered subset of the $\pi$-calculus. To prove the inclusion $\approx_P \subseteq \approx_P^\ell$, we only need to note that all the requisites in the definition of $\approx_P^\ell$ also occur in the definition of $\approx_P$. To prove the converse inclusion we show that $\approx_P^\ell$ is a performance bisimulation. The only point that needs to be checked is the input clause in Proposition 6.1, which is satisfied because $\approx_P^\ell$ is closed under $S_\alpha$-preserving substitutions (Theorem 6.1). $

7. Exponential Distributions

In this section we show how our definitions and results change when only exponential distributions are around. This is actually the only case considered in most papers on Markovian process algebras. We start by remembering what exponential distributions are.

An exponential distribution with rate $r$ is a function $F(t) = 1 - e^{-rt}$, where $t$ is the time parameter. The parameter $r$ determines the shape of the curve. The greater the $r$ parameter, the faster $F(t)$ approaches its asymptotic value. The probability of performing an action with parameter $r$ within time $t$ is $F(t) = 1 - e^{-rt}$, so $r$ determines the time $\Delta t$ needed to obtain a probability near to 1. The exponential density function is $f(t) = re^{-rt}$.

Exponential distributions have the memoryless property. Roughly speaking, transitions occur independently of when the last transition occurred. In other words, how long the transition waits before completion does not depend on how long it has already waited. Thus, the time elapsed by an activity in a state where
another one is the fastest is useless. This means that any time a transition becomes 
enabled, it restarts its elapsing time just as it would the first time it is enabled. 
Consequently, the treatment of enabling memory discipline has no counterpart in 
a pure exponential setting.

Let us discuss how the definition of the cost function $\$ \text{ changes. First, we say } \$
\lambda \in \mathbb{R}^+, \text{ where } \lambda \text{ is the single parameter uniquely describing an exponential }
distribution. Then, $\$ = r \in (0, \infty].$ We can define $\$ as in Sect. 3 by simply 
exchanging $\sum_{\theta \in \Theta} \prod_{\theta \in \Theta}$ to ensure that $\$ \leq 1. Since we will use $r$ as a 
multiplicative factor for $\lambda$ in the definition of $\$, the interval $(0, 1]$ is the domain of 
a slowing-down parameter. Similarly to $\$, we have $f_{[1]}: \mathcal{L}^* \times \mathcal{L}^* \to (0, 1].$ Finally, 
Def. 3.1 becomes

Definition 7.1. The function $\Theta : \Theta \to \mathbb{R}^+$ is defined as

$$
\$(\theta_0, \theta) = \$ \theta_0(\theta) \times \$ \theta(\theta_0)
$$

$$(\theta(0 \alpha_0, \theta_1 \alpha_1)) = f_{[1]}(\theta_0, \theta_1) \times \min\{\$(\theta(0 \alpha_0, \theta_1 \alpha_1))\}
$$

Our knowledge on the kind of distributions we are dealing with enables us to 
simplify the expression of Theorem 3.1. The proof of the following theorem only 
amounts to computing the integrals in Theorem 3.1 by letting $F_i(t)$ be $1 - e^{-\lambda_i t}$.

Theorem 7.1. Given a process $P$,

$$
Rp = \sum_{\theta_i \to P_i} \lambda_i
$$

is the exit rate of $P$. Then, the probability of $P \stackrel{\theta_i \to P_i}{\longrightarrow} P_i$ is

$$
\frac{\lambda_i}{Rp}
$$

the distribution of the random variable $T_i$ which describes the time interval associated 
with $P \stackrel{\theta_i \to P_i}{\longrightarrow} P_i$ is

$$
\tilde{F}_i(t) = 1 - e^{-\lambda_i t};
$$

the apparent rate of an action $a$ in $P$ is

$$
r_a(P) = \frac{1}{Rp} \sum_{\theta_j \to P_j} \lambda_j;
$$

the probability of $P \stackrel{\theta_i \to P_i}{\longrightarrow} P_i$, $\ell(\theta_i) = a$, given that an action $a$ occurred is

$$
\frac{\lambda_i}{\sum_{\theta_j \to P_j} \lambda_j}_{\ell(\theta_j) = a}
$$
We can now instantiate performance bisimulation to exponential distributions. In spite of the interleaving nature of exponential distributions, we still use the structural enabling relation in order to preserve the congruence result of our equivalence. We only need to work on function $\gamma$ in Def. 6.3 by putting any distribution $F_i = 1 - e^{-d_i}$. To make understanding it easier, we denote the resulting function $\hat{\gamma}$.

**Definition 7.2.** The exponential performance bisimulation (written $\approx_p$) is defined as in Def. 6.3 except that function $\gamma$ is replaced by $\hat{\gamma}$, defined by interpreting $\langle P, \xi_i \rangle$ as a singleton equivalence class as follows:

$$\hat{\gamma}(\langle P, \xi \rangle, \theta, C) = \sum_{\langle P, \xi_i \rangle \in C, \ell(\theta_i) = \ell(\theta)} \hat{\gamma}(\langle P, \xi \rangle, \theta, \langle P, \xi_i \rangle) = \sum_{\langle P, \xi_i \rangle \in C, \ell(\theta_i) = \ell(\theta)} r_i,$$

where $r_i$ is the exponential distribution associated with a $P \xrightarrow{\theta_i r_i} P_i$ transition where $\ell(\theta_i) = \ell(\theta)$.

Remember that the condition $Et(\theta) = Et(\theta')$ in the above definition ensures that $\hat{\gamma}$ defines the total conditional transition rate as defined in [30] for PEPA.

We can now show how the exponential performance bisimulation induces a lumpable partition on the underlying Markov process. First we need some auxiliary definitions and lemmas.

**Definition 7.3.** Given a Markov process with state space $\{X_1, X_2, \ldots, X_n\}$, the state space of the aggregated process is some partition $\rho = \{X_1, X_2, \ldots, X_N\}$ with $N < n$ obtained through an equivalence relation on the states of the original process.

A Markov process is lumpable compared to a $\rho$ partition if for every initial distribution the aggregated process is a Markov process.

The following lemma establishes that two exponential performance bisimilar processes have the same total unconditional transition rate of entering a $C$ equivalence class.

**Lemma 7.1.** If $\langle P, \xi \rangle \approx_p \langle Q, \xi' \rangle$ and $p(\langle P, \xi \rangle, C)$ denotes the probability of reaching step a state $P' \in C$ from $P$ in just 1, then

$$\frac{\sum_{\langle P, \xi_i \rangle \in N} \hat{\gamma}(\langle P, \xi \rangle, \theta_i, C)}{\sum_{P \xrightarrow{\theta_i r_i} P_i} r_i} = \frac{\sum_{\langle P, \xi_i \rangle \in N} \hat{\gamma}(\langle Q, \xi' \rangle, \theta_i, C)}{\sum_{Q \xrightarrow{\theta_i r_i} Q_i} r_i}.$$

We eventually prove the lumpability result by defining the state space of a $P$ process as $ds(\langle P, \xi \rangle) = \{\langle P_i, \xi_i \rangle \mid \exists \xi_i = P \xrightarrow{\theta_1 r_1} P_1 \theta_2 r_2 \ldots \theta_i r_i P_i\}$.

**Theorem 7.2.** For any $P$ process, $ds(\langle P, \xi \rangle)_{/\approx_p}$ induces a lumpable partition on the state space of the Markov process which corresponds to $P$.

**Proof.** Let $C_i, C_j \in ds(\langle P, \xi \rangle)_{/\approx_p}$ and consider $P_i', P_i'' \in C_i$. According to Lemma 7.1, it is $\sum_{\ell(\theta_i) \in N} \hat{\gamma}(\langle P_i', \xi \rangle, \theta_i, C_j) = \sum_{\ell(\theta_i) \in N} \hat{\gamma}(\langle P_i'', \xi \rangle, \theta_i, C_j)$ because
$P'_t \approx_P P''_t$. Since [32] proved that a Markov process is lumpable compared to a
\( \rho = \{ X[i] \} \) partition if and only if for any \( X[i], X[j] \in \rho, X_i, X_j \in X[k] \) the total
transition rate from \( X_i \) and \( X_j \) to \( X[k] \) is the same, we have proven the theorem. ■

We now outline how the distribution of synchronizations can be specified in our
approach which is similar to that of the PEPA language. We first recall that a
PEPA-like synchronization rule establishes that the rate of a \( \tau \)-transition between
a \( \langle a, r_0 \rangle \) prefix of a process \( P \) and a \( \langle \tau, r_1 \rangle \) prefix of a process \( Q \) is
\[
r' = \frac{r_0}{R_a(P)} \times \frac{r_1}{R_a(Q)} \times \min\{R_a(P), R_a(Q)\}.
\]
The corresponding transition in the proved semantics is labelled \( \vartheta(\|_{t_0}a, \|_{t_1}\tau) \).
To recover the rate \( r' \) we only need to define
\[
f_t(\|_{t_0}a, \|_{t_1}\tau) = \min\{R_a(P), R_a(Q)\}
\]
with \( \bullet \) of Def. 3.1 being the multiplication. Recall that \( \|_{t_0}a \) and \( \|_{t_1}\tau \) uniquely
identify the sequential components that fire the complementary transitions. Therefore
we can compute \( R_a(P) \) and \( R_a(Q) \) according to Theorem 7.1. Then we replace
\[
\min\{\$\{\vartheta(\|_{t_0}a, \|_{t_1}\tau)\}\}$\)
\]
from Def. 7.1 with \( \$\{\vartheta(\|_{t_0}a, \|_{t_1}\tau)\} \times \$\{\vartheta(\|_{t_1}\tau)\} \times \$\{\vartheta(\|_{t_0}a)\} \) and
define \( \$\{\vartheta(\|_{t_0}a, \|_{t_1}\tau)\} = r_0 \) and \( \$\{\vartheta(\|_{t_1}\tau)\} = r_1 \). Note that \( \vartheta(\|_{t_0}a \) and \( \|_{t_1}\tau \) uniquely
identify the prefix corresponding to the transition. Thus we can define \$ in a tabular way
because the prefixes of a program are finite.

We end this section by referring any reader interested in exponential distributions
to [41, 40, 10] for case studies based on our framework.

8. RELATED WORK

The earliest study of stochastic process algebras with general distributions can
be found in [25], which adds structure to the states of TIPP transition systems.
The operational semantics uses counters to keep track of how many times an
action occurring in a parallel composition has not been selected to happen. Similar
semantics are studied in [9, 31] through a stochastic extension of bundle event
structures with phase-type distributions. This model copes more naturally with general
distributions because activities that are not causally dependent are not related in
the model (as in our approach) contrarily to what happens in interleaving models.
The authors present a process algebra as well whose semantics is defined in terms
of the stochastic event structures. There is also a stochastic extension to LOTOS
where distributions are not limited to exponential ones [2], provided that all the
synchronizations are known at the top level.

A process algebra for discrete event simulation is introduced in [27]. A timer is
set randomly and its expiration determines the actions to be fired. Since urgent and
delayable prefixes are considered, it is possible to cope with both open and closed
systems. A similar approach is presented in [16, 15] for the process algebra Spades
where the finiteness of semantic objects is maintained. There is an expansion law
for decomposing parallel compositions of Spades processes.

A general semi-Markovian process algebra is obtained by working on EMPA in
[7, 8], which interpret processes in ST-semantics which allows for the refinement of
actions. This process algebra represents the GSMP model in a complete way.
The main differences between the approaches above and ours are that they do not cope naturally with mobility and they need to incorporate the stochastic information into the calculus syntax.

Finally, note that the literature presents other attempts at including quantitative information in process algebras for performance evaluation proposed. There are two approaches: the probabilistic and the temporal. Probabilistic process algebras rule out nondeterminism by attaching probabilities to branching points. For instance see [53, 33, 26], but almost all proposals deal with synchronous calculi, thus limiting expressiveness. Temporal process algebras (for a survey see [38]) use time information to evaluate the duration of a specific execution either by associating fixed durations to all actions with the same name or interleaving explicit timed steps with action steps. The absolute duration of actions is sometimes unreal because the time needed by an action heavily depends on the state of resources, the conflicts for accessing them and so on. In any case, the duration of a specific execution does not provide the grounds for a performance evaluation of the whole system.

9. CONCLUSIONS

We have proposed a general framework for handling performance and behavioral analysis within the same model. The uniqueness of the model is a necessary condition to implement our ideas within compiler tools. Our approach is distinctly different from stochastic process algebras because it does not require the designer to know architectural constraints at the time of specification. In fact, no probabilistic information is inserted in the syntax of the language. In spite of this, we can derive the quantitative information we need by looking at the derivation trees of transitions encoded in their labels. The intuitive idea is that the semantic rules correspond to low-level routines of the run-time support of the language. We applied this framework in [41, 40] to model a network management system which yields the same performance results reported in [3] and obtained through informal reasoning. We also studied a distributed data base application and recovered the same quantitative parameter obtained in [13] by informal reasoning. These analyses were carried out by using a tool which implements our framework in an exponential setting [10].

We use the information carried over by our enhanced labels to handle general continuous distributions as well. In particular, we resort to the notion of enabling between transitions [20] to take the history of the system into account. The notion of enabling naturally leads to the enabling memory discipline for selecting which transitions to fire [1]. We prove that this notion works properly with limited resources. Under a maximal parallelism assumption (unbound resources), we refined the enabling memory discipline so that the history of the system is no longer needed even for general continuous distributions. The main reason is that a transition is either fired as soon as it becomes enabled or it is discarded.

Our current studies concern refinement of the definition of function $\$\$ to obtain sensible transition costs and to characterize its algebraic properties. We also plan to extend this framework to real distributed languages and to test how it is scalable on real applications. Furthermore, we implemented a stochastic version of the full $\pi$-calculus to simulate the behavior of complex systems [49, 48].
As a further investigation, it would be interesting to see how generalized semi-Markov processes, which are receiving great attention in the literature relate to our approach.

This paper is a further step towards defining a kernel of an integrated environment for creating distributed and mobile systems. To this purpose, we feel it is essential not to modify the syntax of the language in order to retrieve or restore the information needed to carry out both qualitative and quantitative analyses. This amounts to saying that the designer of a system only needs to know the syntax of the (specification) language. Implementation-dependent information is encoded in the compiler. Furthermore, the topic of this paper further stresses the motto proof as transitions described in [19] where the authors claim that enhanced labels encode almost all the information needed for software development.

ACKNOWLEDGMENTS

The Author thanks Giandomenico Orlandi for his suggestions on the mathematical treatment of the homotety of arguments. The Author also thanks Paola Siri and Stefania Ugolini for their help on probabilistic matters. Finally, the Author is grateful to the reviewers for their precise and valuable comments.
